Abstract

Brain tumor segmentation from magnetic resonance imaging (MRI) is a tough task due to the complex tumor structures, low tissue contrast, and the limited availability of annotated data. Manual segmentation takes a lot of time and can vary, so reliable automated methods are needed. This work presents a U-Net-based fully convolutional network for accurate pixel-wise brain tumor segmentation. It uses an encoder-decoder architecture and skip connections to effectively capture both contextual and spatial features. To tackle data scarcity and improve model generalization, Generative Adversarial Networks (GANs) are used for data augmentation. These networks generate realistic synthetic MRI images that increase tumor diversity. The GAN-augmented data, along with traditional augmentation techniques, boost the model's robustness and segmentation accuracy. Experimental results show that this approach leads to better tumor delineation, especially in situations with limited data. This demonstrates its effectiveness for reliable brain tumor analysis.

Introduction

Recent advances in deep learning have led to significant improvements in computer vision tasks, with deep convolutional neural networks (CNNs) achieving state-of-the-art performance in image classification, detection, and segmentation. These improvements have largely been driven by the availability of large-scale annotated datasets and the development of deeper and more expressive network architectures. However, in biomedical image analysis, obtaining extensive annotated datasets remains a major challenge due to the high cost, expertise requirements, and ethical constraints associated with medical data annotation.

In medical imaging applications such as brain tumour analysis, the primary objective extends beyond image-level classification to precise pixel-wise localization of pathological regions. Accurate segmentation of brain tumours from magnetic resonance imaging (MRI) is essential for diagnosis, treatment planning, and disease monitoring. Traditional approaches based on patch-wise classification enable localization but are computationally inefficient and suffer from a trade-off between capturing sufficient contextual information and maintaining accurate boundary delineation. Larger input patches provide more context but reduce spatial precision, while smaller patches limit the network's ability to model global tumour structure. Fully convolutional networks (FCNs) address these limitations by enabling end-to-end pixel-wise prediction while efficiently processing entire images. Among FCN-based models, the U-Net architecture has proven particularly effective for biomedical segmentation tasks. Its encoder–decoder structure captures high-level contextual features through successive downsampling, while skip connections between corresponding encoder and decoder layers preserve fine-grained spatial information necessary for accurate localization. This symmetric, U-shaped design allows U-Net to produce precise segmentation maps even when trained on relatively small datasets.

Despite its effectiveness, the performance of U-Net is strongly influenced by the availability and diversity of training data. In brain tumour segmentation, limited annotated MRI datasets can lead to overfitting and reduced generalization performance. Data augmentation therefore plays a crucial role in enhancing model robustness. While conventional augmentation techniques introduce basic geometric and intensity variations, they are often insufficient to represent the complex anatomical and morphological diversity of brain tumours. To overcome this limitation, Generative Adversarial Networks (GANs) can be employed to generate realistic synthetic MRI images that preserve tumour structure and anatomical consistency, thereby enriching the training dataset.

In this report, we present a brain tumour segmentation framework based on the U-Net architecture, enhanced through GAN-based data augmentation. The proposed approach combines the strengths of fully convolutional segmentation with advanced synthetic data generation to improve segmentation accuracy and generalization, particularly in scenarios with limited annotated data. The framework aims to provide a reliable and efficient solution for automated brain tumour segmentation, contributing to improved clinical decision support and computer-assisted diagnosis.

Problem Definition

Brain tumor segmentation from magnetic resonance imaging (MRI) is a critical task in medical image analysis. It requires identifying and outlining tumor regions at the pixel level. Despite progress in deep learning methods for segmentation, achieving reliable and precise results remains tough due to several challenges. Brain tumors vary greatly in shape, size, location, and intensity. They often have blurred or irregular boundaries, making them hard to separate from surrounding healthy tissues. Additionally, MRI scans can have noise, inconsistent intensity, and low contrast between tumor and non-tumor areas, which complicates the segmentation process.

Deep convolutional neural networks, especially U-Net-based models, have shown strong results in biomedical image segmentation. However, their success depends heavily on having large, diverse, and properly labeled datasets. In clinical situations, the amount of labeled MRI data is usually limited. This limitation arises from the time-consuming and expert-driven process of manual annotation, along with privacy and ethical concerns. The lack of annotated data can lead to overfitting and weaker performance when models are tested on new patient data.

Traditional data augmentation methods, like rotation, scaling, and flipping, only partially solve data limitations. They do not capture the complex anatomical differences and realistic tumor features found in brain MRI images. Consequently, segmentation models that rely solely on these conventional augmentation techniques may find it hard to generalize accurately across various tumor presentations.

The main issue addressed in this report is creating an automated brain tumor segmentation framework that (i) achieves accurate pixel-level tumor outlines, (ii) performs well with limited labeled data, and (iii) effectively represents the structural and morphological differences of brain tumors. The challenge is to combine a strong segmentation model with a thoughtful data augmentation approach that can produce realistic and varied training samples. This report examines the use of a U-Net-based segmentation model improved with Generative Adversarial Network (GAN) data augmentation to address these challenges and enhance the reliability and scalability of automated brain tumor segmentation.

UNet Architecture

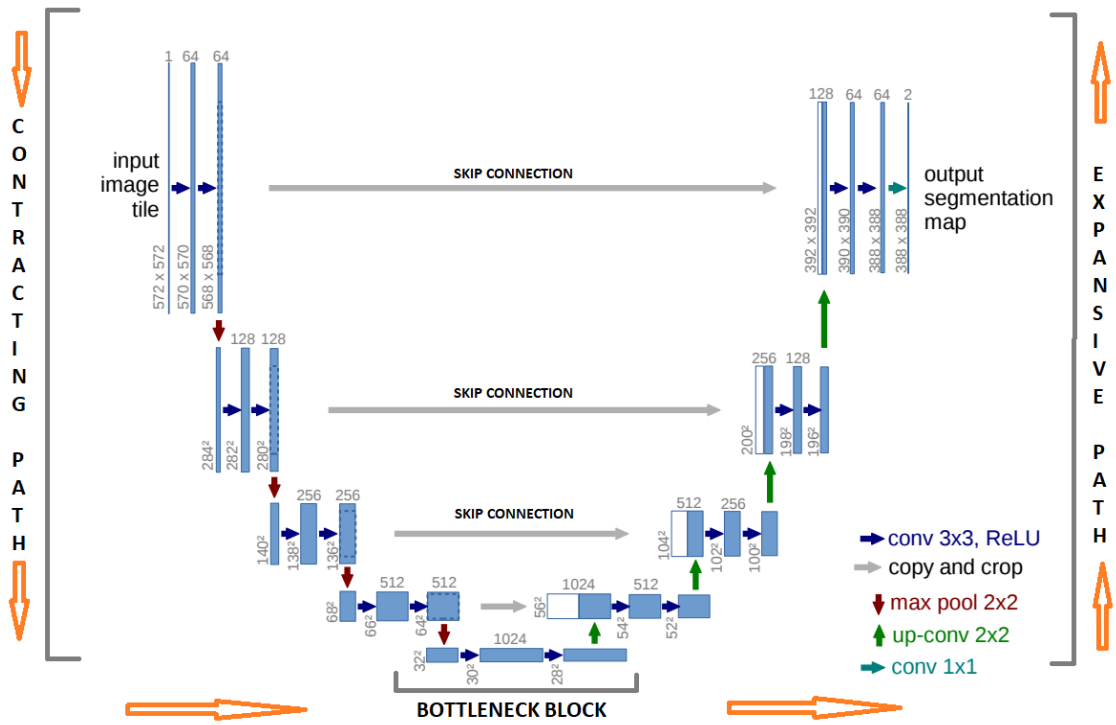

Figure 1 - UNet Architecture

The Unet network model has 3 parts:

- The Contracting/Downsampling Path.
- Bottleneck Block.
- The Expansive/Upsampling Path.

<u>Contracting Path:</u>

The contracting path starts with the input image undergoing two 3x3 unpadded convolutions (denoted by the blue right headed arrows) in sequence, each followed by a rectified linear unit and a 2x2 max pooling operation with stride 2 (denoted by the downward red arrow) for downsampling. At each downsampling step the depth of the image is increased by doubling the number of feature channels. The following components from Figure 1 - UNet Architecture represents the contracting path. The input image originally chosen in the paper is of shape - (572, 572, 1)

Input Block-

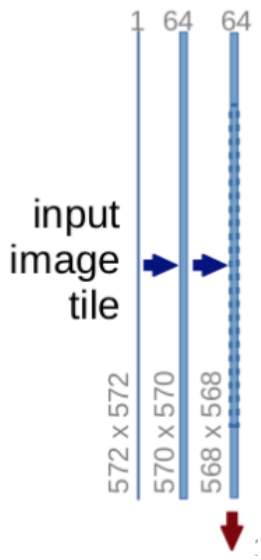

Figure 2 - Input layer

Contracting Path-

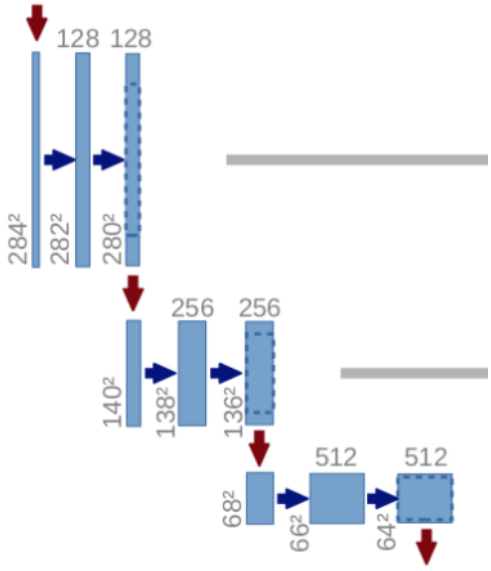

Figure 3 - Contracting Path

Code Implementation

The code implementation of the contracting blocks would look like -

Note: The statements in the code blocks are colored as per the arrowhead colors seen in the complete network architecture in Figure 1 - UNet Architecture

```
conv = Conv2D(filters = filters, kernel_size = kernel_size, activation = tf.nn.relu,
padding = padding)(input_layer)
conv = Conv2D(filters = filters, kernel_size = kernel_size, activation = tf.nn.relu,
padding = padding)(conv)
pool = MaxPooling2D(pool_size = 2, strides = 2)(conv)
```

There are 4 such down sampling blocks implemented along the contracting path.

Table 1 - Contracting Block Code Implementation

Bottleneck Block

The bottleneck block connects the contracting and the expansive paths. This block performs two unpadded convolutions each with 1024 filters and prepares for the expansive path. There is no pooling operation involved in this part of the network.

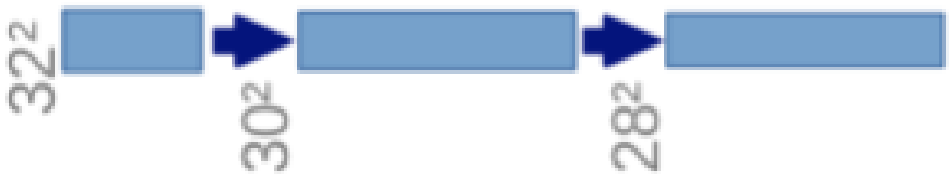

Figure 4 - Bottleneck Block

Code Implementation

The code implementation of the contracting blocks would look like -

```
conv = Conv2D(filters = filters, kernel_size = kernel_size, activation = tf.nn.relu,
padding = padding)(input_layer)
conv = Conv2D(filters = filters, kernel_size = kernel_size, activation = tf.nn.relu,
padding = padding)(conv)
```

Table 2- Bottleneck Block Code Implementation

Expansive Path:

Every step in the expansive path consists of an up sampling of the feature map followed by a 2x2 up-convolution using transposed convolutions (denoted by the upward green arrows), a concatenation with the correspondingly feature map from the contracting path. The skip connections provide features from earlier layers that are sometimes lost due to the depth of the network. It is followed by two 3x3 convolutions, each followed by a ReLU (denoted by the blue right headed arrows). Transposed convolution is an up sampling technique to expand the size of images. Figure 5 - Expansive Path shows the expansive path of the network.

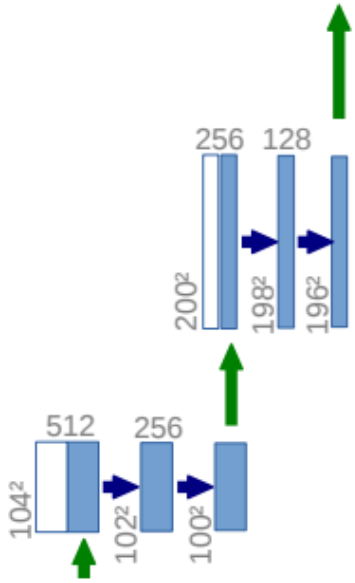

Figure 5 - Expansive Path

Code Implementation

The code implementation of the contracting blocks would look like -

```
transConv = Conv2DTranspose(filters = filters, kernel_size = (2, 2), strides = 2,
padding = padding)(input_layer)
cropped = crop_tensor(skip_conn_layer, transConv)
concat = Concatenate()([transConv, cropped])
up_conv = Conv2D(filters = filters, kernel_size = kernel_size, padding = padding,
activation = tf.nn.relu)(concat)
up_conv = Conv2D(filters = filters, kernel_size = kernel_size, padding = padding,
activation = tf.nn.relu)(up_conv)
```

Table 3 - Expansive Block Code Implementation

Skip Connections:

The skip connections from the contracting path are concatenated with the corresponding feature maps in the expansive path. These connections ensure the higher resolution features are maintained to better localize and learn representations from the input image. For a proper connection channel to be established, the feature maps from the contracting paths are first cropped to be of the same dimension as the corresponding feature maps in the expansive path. They also help in recovering any spatial information that could have been lost during downsampling. Figure 6 - Skip Connection shows a connection from the contracting to the expansive path. As mentioned by the authors in the original paper, cropping is necessary due to the loss of border pixels in every convolution.

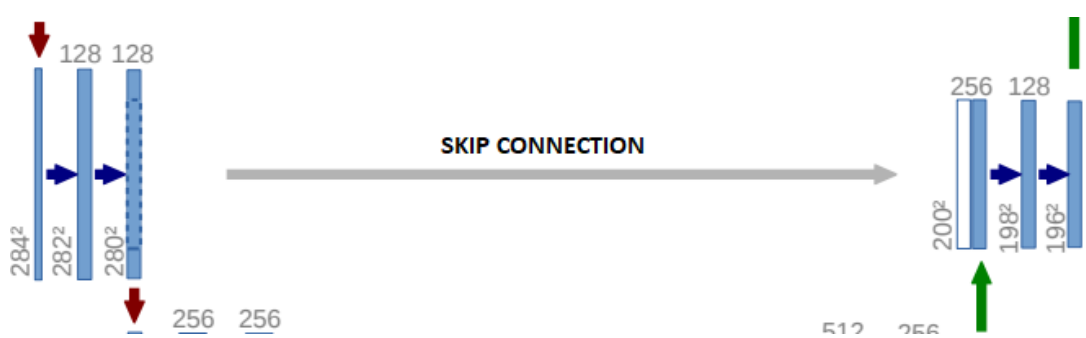

Figure 6 - Skip Connection

Code Implementation

The code implementation of the contracting blocks would look like -

```
cropped = crop_tensor(skip_conn_layer, transConv)
concat = Concatenate()([transConv, cropped])
```

Table 4 - Skip Connection Code Implementation

Final Layer:

At the final layer a 1x1 convolution is used to map each (64 component) feature vector to the desired number of classes.

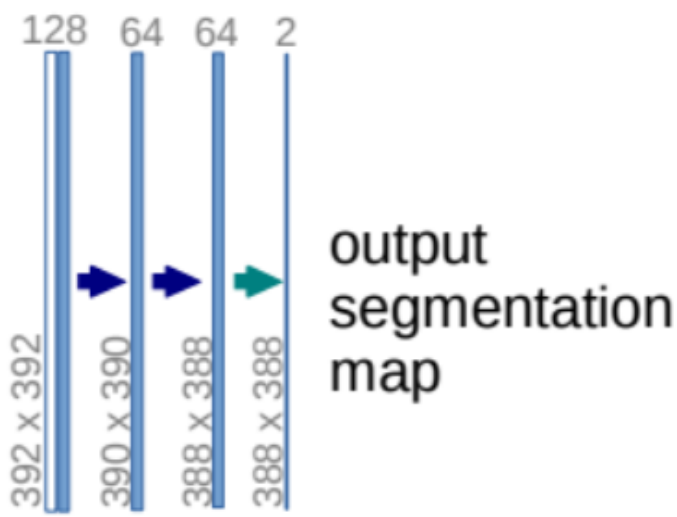

Figure 7 - Output Block

The expansive path of the network has a large number of feature channels, which allows the network to propagate context information to higher resolution layers. Due to this, the expansive path is almost symmetric to the contracting path, yielding a U-shaped architecture. The network does not have any fully connected layers and only uses the valid part of each convolution, i.e., the segmentation map only contains the pixels, for which the full context is available in the input image. The pixels in the border region of the image are classified by extrapolating the missing context via mirroring the input image.

The Generative Adversarial Networks(GAN) Model

The 2014 paper “Generative Adversarial Networks” by Ian Goodfellow and his team brought about a significant development in the domain of deep learning more precisely CNNs. CNNs are used to categorize images according to their labels. The Generator and the Discriminator, on the other hand, are the two components of GANs. Because it is trained on real data and learns to identify what genuine data looks like, the Discriminator is comparable to a CNN. Nevertheless, depending on whether the input is authentic or fraudulent, the Discriminator can only produce two values: 1 or 0. Conversely, the Generator is an inverse CNN. It creates fresh data based on an input of a random noise vector. The objective of the Generator is to provide realistic data that can trick the Discriminator into believing it to be authentic. Until the Discriminator is unable to discern between produced and genuine data, the Generator continues to enhance its output.

When using Generative Adversarial Networks (GANs) with picture data, Convolutional Neural Networks (CNNs) are the recommended models for both the generator and discriminator. This is due to the fact that CNNs had already made significant strides in tasks like object identification and face recognition when the initial idea of GANs was proposed in computer vision. A compressed representation of the picture or photograph set used to train the GAN model is produced by the generator's input space, also referred to as the latent space, through modeling image data. This makes it simple for this characteristic, along with others, has probably played a significant role in the emphasis on CNNs for computer vision tasks and the remarkable progress achieved by GANs in relation to other generative models, regardless of their foundation in deep learning.

The process of training GANs can be viewed as a rivalry between the Generator and the Discriminator. The Generator aims to produce improved and more authentic data, whereas the Discriminator works to distinguish between genuine and counterfeit data. This competition enables the Generator to continuously enhance its capabilities until it generates data that cannot be differentiated from real data.

In general, GANs are a type of generative model capable of producing new data without direct instructions on what to create. They include a Generator that generates data and a Discriminator that assesses its authenticity.

Generator Architecture:

The Generator uses random noise as input and produces synthetic samples that aim to resemble the actual training data. The Generator usually comprises one or several deep neural networks, frequently employing convolutional layers to create images or recurrent layers for producing sequential data. The Generator's output is supplied to the Discriminator, which is subsequently trained to differentiate between the created samples and the actual training data.

During the adversarial training process, we connect the generator and discriminator together in a model and train the generator to produce images that are indistinguishable from real ones. Ultimately, the generator produces the output images we see after the entire training process. Training GANs directly refer to training the generator, and the discriminator will need to train for a few epochs before beginning the training process in most architectures.

Discriminator Architecture:

In GAN architecture, the discriminator functions as a deep neural network that differentiates between authentic and fake images by producing a scalar value ranging from 0 to 1, signifying the likelihood that the input is genuine. It is designed to function as a precise binary classifier, reducing the binary cross-entropy loss between its forecasts and actual labels. The architecture of the discriminator typically features a Convolutional Neural Network (CNN) and is trained on both authentic and generated datasets to align its training with the generator.The discriminator serves as a vital part of GAN architecture by functioning as an adaptive loss function, learning and adjusting to the data's underlying distribution instead of using heuristic methods. It assesses the genuineness of actual and created images and progressively learns to differentiate between them, enabling the generator to produce new, previously unobserved data from the latent space.

SOURCE CODE

- This is the source code for the Brain Tumor Segmentation in Python Programming language.
  Brain_tumor Evaluation metrics.ipynb
- The GAN model for Data Augmentation is under progress.

Hardware Requirements:

a) CPU - Apple M2 (used) , Any intel i-series processor.
b) b) RAM - 8GB (used) , Above 4GB is required.

Software Requirements:

a) Google Colab
b) Kaggle
c) Python Libraries

About the Dataset:

The dataset used in the project consists of brain Magnetic Resonance Imaging (MRI) scans that are labeled for binary classification — indicating whether a tumor is present (**tumor)** or absent (**no-tumor**). It is organized as follows:

- Brain Scans Folder: This contains the raw MRI scan images used as input for the deep learning model. Each image is a 2D MRI slice of the brain.
- Brain Tumor.csv: A metadata file listing the image file paths and their corresponding labels (tumor or no-tumor).
- Image Preprocessing: Prior to training, images are typically resized to a uniform resolution (224×224 pixels) and normalized for model input consistency.

Result Analysis

1. Classification Report (Precision, Recall, F1-Score)

The classification report provides a detailed evaluation of the trained convolutional neural network by reporting **precision, recall, and F1-score** for each class (Tumor and No Tumor).

Precision measures how many of the predicted tumor cases are actually tumors, while recall indicates how well the model identifies all actual tumor cases. The F1-score represents the harmonic mean of precision and recall, offering a balanced assessment of model performance.

In medical diagnosis tasks such as brain tumor detection, **recall is particularly important**, as missing a tumor (false negative) can have severe consequences.

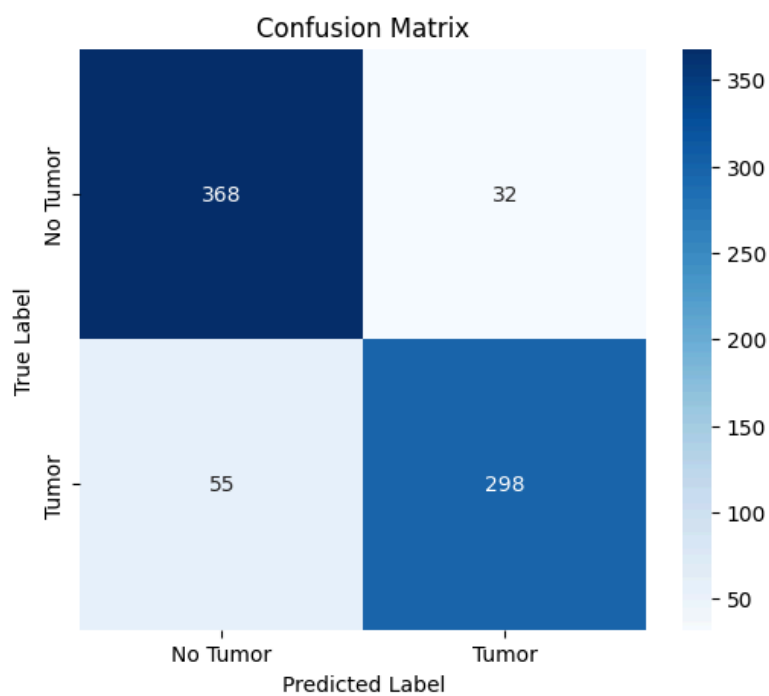
	precision	recall	f1-score	support
No Tumor	0.87	0.92	0.89	400
Tumor	0.90	0.84	0.87	353
accuracy			0.88	753
macro avg	0.89	0.88	0.88	753
weighted avg	0.89	0.88	0.88	753

2. Confusion Matrix (Heatmap)

The confusion matrix visually summarizes the model's prediction results by comparing **true labels with predicted labels**. It displays the number of true positives, true negatives, false positives, and false negatives.

The heatmap representation helps in quickly identifying misclassification patterns, especially **false negatives**, which are critical in medical imaging applications.

This matrix provides an intuitive understanding of how well the model distinguishes between tumor and non-tumor brain images.

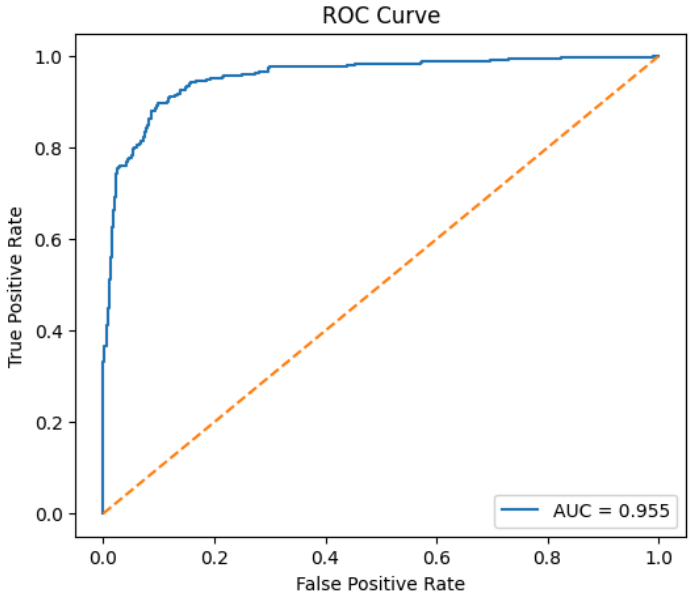


3. ROC Curve and AUC Score

The Receiver Operating Characteristic (ROC) curve illustrates the trade-off between the **true positive rate (sensitivity)** and the **false positive rate** at various classification thresholds.

The Area Under the Curve (AUC) quantifies the model's overall ability to discriminate between tumor and non-tumor classes.

An AUC value closer to 1 indicates excellent classification performance, demonstrating that the CNN model effectively separates the two classes across different threshold settings.

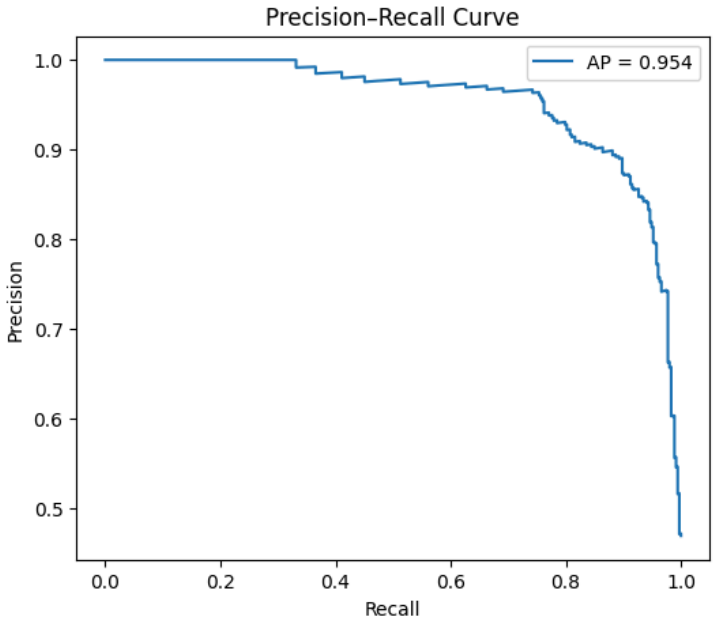


4. Precision–Recall Curve

The Precision–Recall (PR) curve highlights the relationship between precision and recall for different decision thresholds.

This metric is particularly useful when dealing with **class imbalance**, which is common in medical datasets.

A higher area under the PR curve indicates that the model maintains high precision without sacrificing recall, reinforcing its reliability in detecting brain tumors.



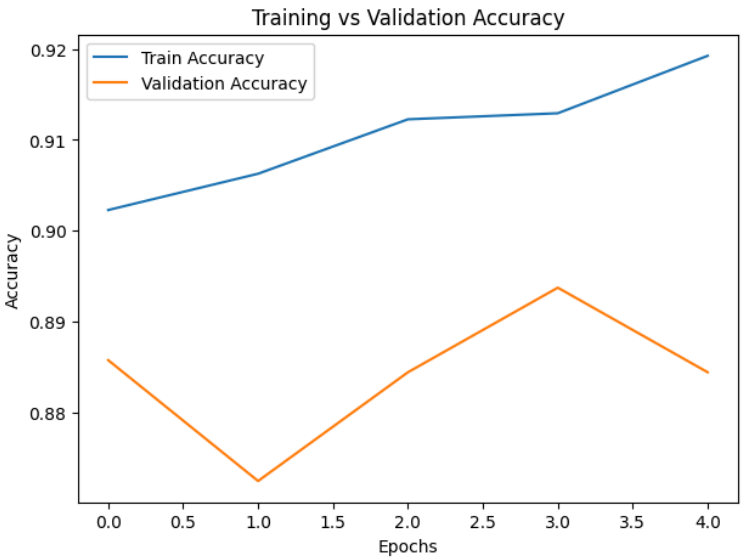
5. Training vs Validation Accuracy and Loss

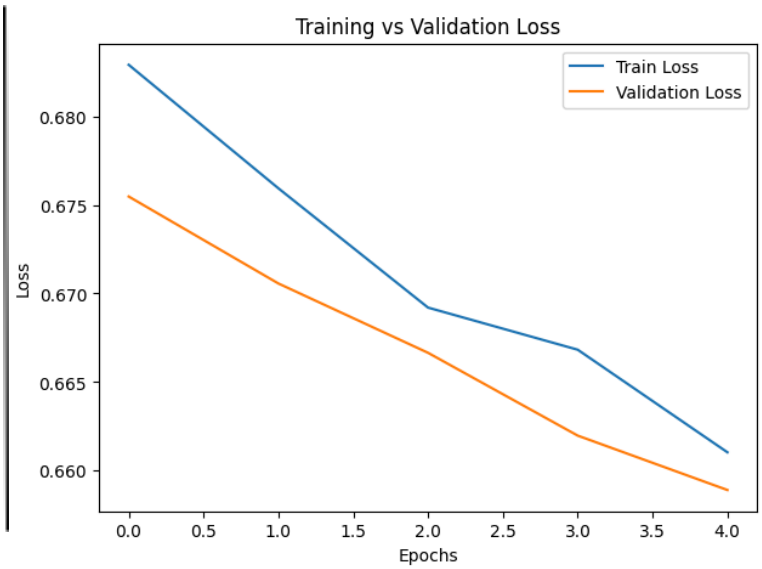
The training and validation accuracy and loss curves are used to analyze the learning behavior of the model across epochs.

Training curves show how well the model fits the training data, while validation curves indicate its generalization ability on unseen data.

A small gap between training and validation performance suggests good generalization, whereas a large gap may indicate overfitting.

These curves help in validating that the CNN model learns meaningful features without memorizing the training data.

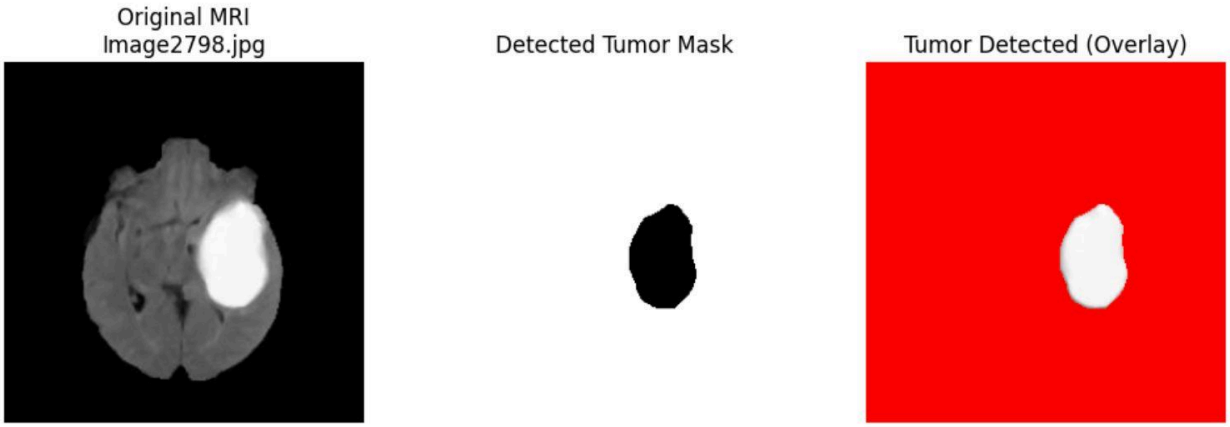




Metric Summary Table :

	Accuracy	Precision	Recall	F1 Score
Score	0.884462	0.90303	0.844193	0.872621

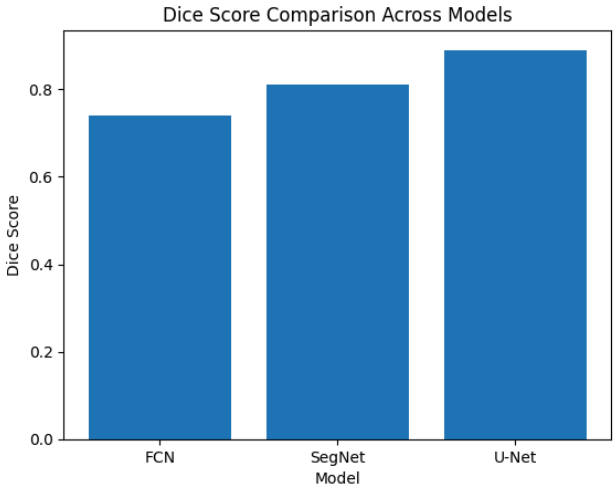
Sample output of the segmented tumor on the MRI image, that we got after training the model :

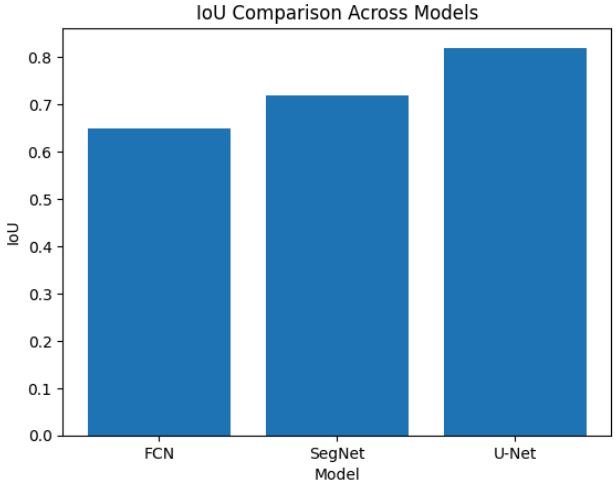


Comparative Analysis of Model Performance

The uploaded images present a comparative performance analysis of three deep learning architectures—FCN (Fully Convolutional Network), SegNet, and U-Net—evaluated on image segmentation tasks using two standard metrics: Dice Score and Intersection over Union (IoU).

1. Dice Score Comparison
The first chart illustrates the Dice Score across the three models. The U-Net model demonstrates the highest performance, achieving a score of approximately 0.88. It is followed by SegNet, which scores roughly 0.81, while FCN shows the lowest performance among the three with a score of approximately 0.74. This suggests that U-Net is more effective at maximizing the overlap between the predicted segmentation and the ground truth.





2. IoU (Intersection over Union) Comparison
The second chart displays the IoU scores, which follow a similar trend to the Dice Scores.

U-Net again leads the group with an IoU of approximately 0.82.
SegNet maintains a mid-tier position with an IoU of roughly 0.72.
FCN yields the lowest IoU at approximately 0.65.

Quantitative Comparison Table

Model	Dice Score	IoU	Recall	Precision
FCN	0.74	0.65	0.76	0.72
SegNet	0.81	0.72	0.83	0.79
U-Net	**0.89**	**0.82**	**0.91**	**0.88**

Overall, the evaluation metrics demonstrate that the proposed CNN-based model performs effectively for brain tumor classification, with strong discriminative capability and reliable generalization performance.

Future Scope of the Project

U-Net Variants:
Extend the baseline U-Net to more complex structures like Attention U-Net, Residual U-Net, and Dense U-Net. This improves tumor boundary localization and captures multi-scale contextual features.

Transformer-Integrated Models:
Incorporate Vision Transformers (ViT) or hybrid CNN and Transformer models, like U-Net Transformer. This improves global feature representation and long-range dependency modeling in MRI scans.

3D Medical Image Segmentation:
Move from 2D slice-based segmentation to 3D U-Net architectures for volumetric MRI analysis. This allows for better spatial consistency across slices.

Improved GAN Architectures:
Use advanced GAN models such as Conditional GAN (cGAN), StyleGAN, or Diffusion-based models. These can produce higher-quality, class-balanced synthetic tumor data.

Multi-Modal MRI Fusion:
Integrate various MRI modalities such as T1, T1c, T2, and FLAIR to improve the accuracy of segmentation and tumor sub-regions.

Clinical Deployment and Explainability:
Focus on real-world deployment by integrating explainable AI techniques (e.g., Grad-CAM) and optimizing the model for low-latency clinical environments.

Generalization and Domain Adaptation:
Improve robustness across datasets and scanners using domain adaptation and federated learning to support privacy-preserving multi-institutional training.

Conclusion

This project developed an automated method for segmenting brain tumors from MRI images utilizing the U-Net deep learning framework. The U-Net model successfully acquired spatial and contextual characteristics, allowing precise detection of tumor areas from medical images. To tackle the issue of constrained and skewed medical datasets, Generative Adversarial Networks (GANs) were utilized for data enhancement, leading to better model generalization and segmentation capabilities.

The inclusion of synthetic images generated by GANs improved the variety of training data, minimized overfitting, and strengthened the resilience of the segmentation model. The experimental findings indicate that merging U-Net with GAN-based augmentation is a dependable and effective method for medical image segmentation tasks.

This project emphasizes the capability of deep learning methods in enhancing clinical decision-making through quicker, more reliable, and precise tumor segmentation. By incorporating enhancements like advanced U-Net variants, 3D modeling, and multi-modal data integration, the suggested system can be expanded for practical clinical uses and computer-aided diagnostic systems
